Ad hoc On-Demand Distance Vector (AODV) Routing
draft-ietf-manet-aodv-07.txt

Status of This Memo

Abstract

The Ad Hoc On-Demand Distance Vector (AODV) routing protocol is intended for use by mobile nodes in an ad hoc network. It offers quick adaptation to dynamic link conditions, low processing and memory overhead, low network utilization, and determines unicast

between sources and destinations. It uses destination sequence numbers to ensure loop freedom at all times (even in the face of anomalous delivery of routing control messages), solving problems (such as ‘‘counting to infinity’’) associated with classical distance vector protocols.

Contents

1. Introduction

The Ad Hoc On-Demand Distance Vector (AODV) algorithm enables dynamic, self-starting, multihop routing between participating mobile nodes wishing to establish and maintain an ad hoc network. AODV allows mobile nodes to obtain routes quickly for new destinations, and does not require nodes to maintain routes to destinations that are not in active communication. AODV allows mobile nodes to respond quickly to link breakages and changes in network topology. The operation of AODV is loop-free, and by avoiding the Bellman-Ford ''counting to infinity'' problem offers quick convergence when the ad hoc network topology changes (typically, when a node moves in the network). When links break, AODV causes the affected set of nodes to be notified so that they are able to invalidate the routes using the broken link.

One distinguishing feature of AODV is its use of a destination sequence number for each route entry. The destination sequence number is created by the destination for any route information it sends to requesting nodes. Using destination sequence numbers ensures loop freedom and is simple to program. Given the choice between two routes to a destination, a requesting node always selects the one with the greatest sequence number.

2. Overview

Route Requests (RREQs), Route Replies (RREPs), and Route Errors (RERRs) are the message types defined by AODV. These message types are handled by UDP, and normal IP header processing applies. So, for instance, the requesting node is expected to use its IP address as the source IP address for the messages. The range of dissemination of broadcast RREQs can be indicated by the TTL in the IP header. Fragmentation is typically not required.

As long as the endpoints of a communication connection have valid routes to each other, AODV does not play any role. When a route to a new destination is needed, the node uses a broadcast RREQ to find a route to the destination. A route can be determined when the RREQ reaches either the destination itself, or an intermediate node with a 'fresh enough' route to the destination. A 'fresh enough' route is an unexpired route entry for the destination whose associated sequence number is at least as great as that contained in the RREQ. The route is made available by unicasting a RREP back to the source of the RREQ. Since each node receiving the request caches a route back to the source of the request, the RREP can be unicast back from the destination to the source, or from any intermediate node that is able to satisfy the request back to the source. A RREQ can be conditioned by requirements on the path to the destination, namely bandwidth or delay bounds.

Nodes monitor the link status of next hops in active routes. When a link break in an active route is detected, a RERR message is used to notify other nodes that the loss of that link has occurred. The RERR message indicates which destinations are now unreachable due to the loss of the link.

AODV is a routing protocol, and it deals with route table management. Route table information must be kept even for ephemeral routes, such as are created to temporarily store reverse paths towards nodes originating RREQs. AODV uses the following fields with each route table entry:

- Destination IP Address
- Destination Sequence Number
- Interface

- Hop Count (number of hops needed to reach destination)
- Last Hop Count (described in subsection 8.2.1)
- Next Hop
- List of Precursors (described in Section 8.1)
- Lifetime (expiration or deletion time of the route)
- Routing Flags

3. AODV Terminology

This protocol specification uses conventional meanings [1] for capitalized words such as MUST, SHOULD, etc., to indicate requirement levels for various protocol features. This section defines other terminology used with AODV that is not already defined in [3].

active route

A routing table entry with a finite metric in the Hop Count field. A routing table may contain entries that are not active (invalid routes or entries). They have an infinite metric in the Hop Count field. Only active entries can be used to forward data packets. Invalid entries are eventually deleted.

forwarding node

A node which agrees to forward packets destined for another destination node, by retransmitting them to a next hop which is closer to the unicast destination along a path which has been set up using routing control messages.

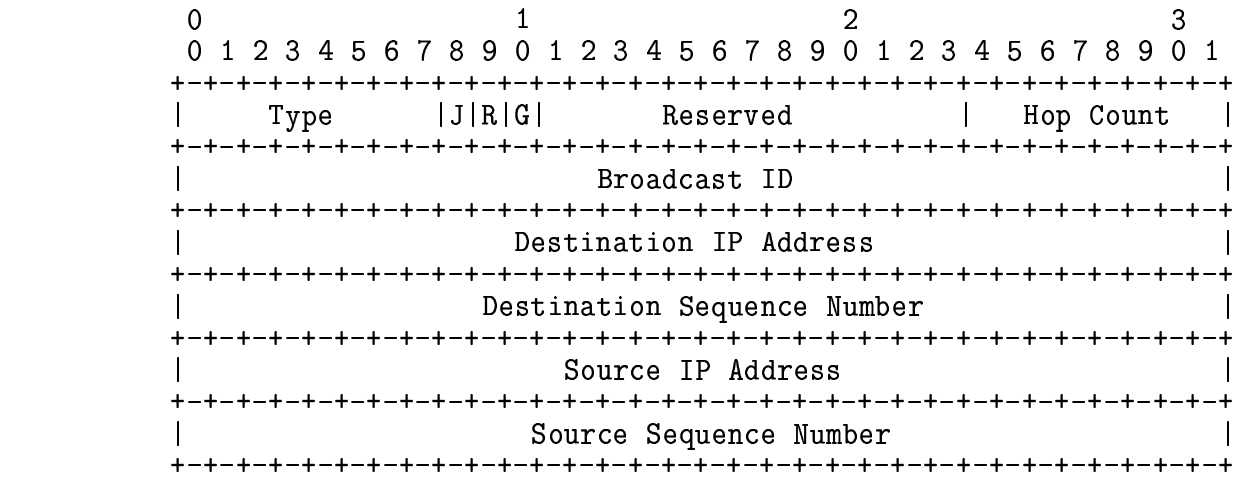
forward route

A route set up to send data packets from a source to a destination.

reverse route

A route set up to forward a reply (RREP) packet back to the source from the destination or from an intermediate node having a route to the destination.

4. Route Request (RREQ) Message Format



The format of the Route Request message is illustrated above, and contains the following fields:

Type	1
J	Join flag; reserved for multicast.
R	Repair flag; reserved for multicast.
G	Gratuitous RREP flag; indicates whether a gratuitous RREP should be unicast to the node specified in the Destination IP Address field (see sections 8.2, 8.5)
Reserved	Sent as 0; ignored on reception.

Hop Count
: The number of hops from the Source IP Address to the node handling the request.

Broadcast ID
: A sequence number uniquely identifying the particular RREQ when taken in conjunction with the source node's IP address.

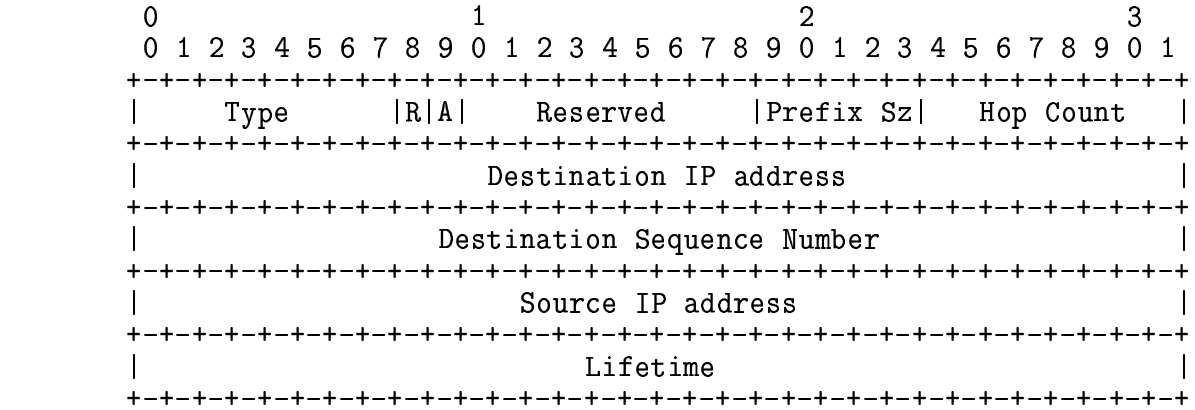
Destination IP Address
: The IP address of destination for which a route is desired.

Destination Sequence Number
: The last sequence number received in the past by the source for any route towards the destination.

Source IP Address
: The IP address of the node which originated the Route Request.

Source Sequence Number
: The current sequence number to be used for route entries pointing to (and generated by) the source of the route request.

5. Route Reply (RREP) Message Format



The format of the Route Reply message is illustrated above, and contains the following fields:

Type 2

R Repair flag; used for multicast.

A Acknowledgment required; see sections 7 and 8.6.

Reserved Sent as 0; ignored on reception.

Prefix Size If nonzero, the 5-bit Prefix Size specifies that the indicated next hop may be used for any nodes with the same routing prefix (as defined by the Prefix Size) as the requested destination.

Hop Count The number of hops from the Source IP Address to the Destination IP Address. For multicast route requests this indicates the number of hops to the multicast tree member sending the RREP.

Destination IP Address
The IP address of the destination for which a route is supplied.

Destination Sequence Number
The destination sequence number associated to the route.

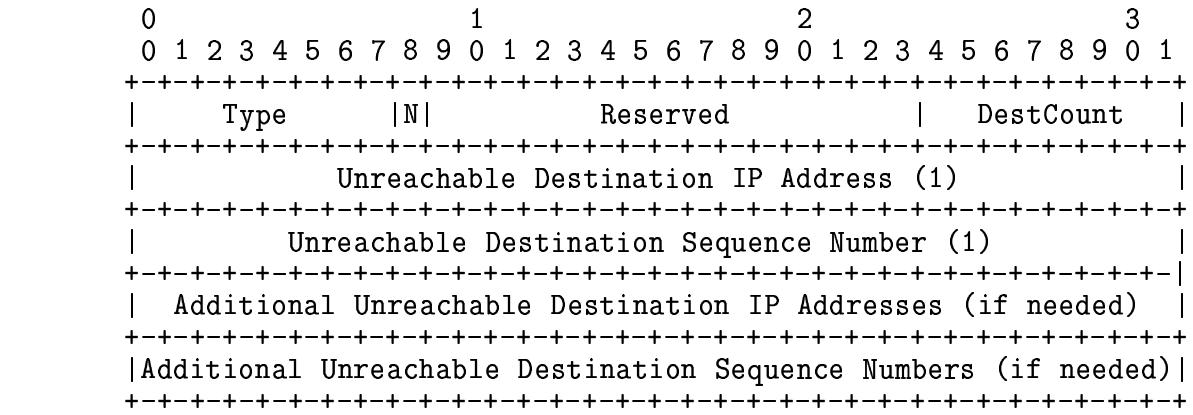
Source IP Address
The IP address of the source node which issued the RREQ for which the route is supplied.

Lifetime The time for which nodes receiving the RREP consider the route to be valid.

Note that the Prefix Size allows a Subnet Leader to supply a route for every host in the subnet defined by the routing prefix, which is determined by the IP address of the Subnet Leader and the Prefix Size. In order to make use of this feature, the Subnet Leader has to guarantee reachability to all the hosts sharing the indicated subnet

prefix. The Subnet Leader is also responsible for maintaining the Destination Sequence Number for the whole subnet.

6. Route Error (RERR) Message Format



The format of the Route Error message is illustrated above, and contains the following fields:

Type 3

N No delete flag; set when a node has performed a local repair of a link, and upstream nodes should not delete the route.

Reserved Sent as 0; ignored on reception.

DestCount The number of unreachable destinations included in the message; MUST be at least 1.

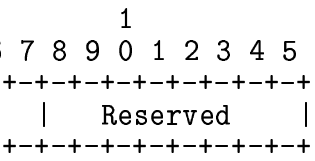
Unreachable Destination IP Address
The IP address of the destination which has become unreachable due to a link break.

Unreachable Destination Sequence Number
The last known sequence number, incremented by one,

of the destination listed in the previous Unreachable Destination IP Address field.

The RERR message is sent whenever a link break causes one or more destinations to become unreachable. The unreachable destination addresses included are those of all lost destinations which are now unreachable due to the loss of that link.

7. Route Reply Acknowledgment (RREP-ACK) Message Format



Type 4

Reserved Sent as 0; ignored on reception.

The RREP-ACK message is used to acknowledge receipt of a RREP message. It is used in cases where the link over which the RREP message is sent may be unreliable.

8. AODV Operation

This section describes the scenarios under which nodes generate RREQs, RREPs and RERRs for unicast communication, and how the message data are handled.

8.1. Maintaining Route Utilization Records

For each valid route maintained by a node (containing a finite Hop Count metric) as a routing table entry, the node also maintains a list of precursors that may be forwarding packets on this route. These precursors will receive notifications from the node in the event of detection of the loss of the next hop link. The list of

precursors in a routing table entry contains those neighboring nodes to which a route reply was generated or forwarded.

Each time a route is used to forward a data packet, its Lifetime field is updated to be current time plus ACTIVE_ROUTE_TIMEOUT.

8.2. Generating Route Requests

A node broadcasts a RREQ when it determines that it needs a route to a destination and does not have one available. This can happen if the destination is previously unknown to the node, or if a previously valid route to the destination expires or is broken (i.e., an infinite metric is associated with the route). The Destination Sequence Number field in the RREQ message is the last known destination sequence number for this destination and is copied from the Destination Sequence Number field in the routing table. If no sequence number is known, a sequence number of zero is used. The Source Sequence Number in the RREQ message is the node's own sequence number. The Broadcast ID field is incremented by one from the last broadcast ID used by the current node. Each node maintains only one broadcast ID. The Hop Count field is set to zero.

A source node often expects to have bidirectional communications with a destination node. In such cases, it is not sufficient for the source node to have a route to the destination node; the destination must also have a route back to the source node. In order to cause this to happen as efficiently as possible, any generation of an RREP by an intermediate node (as in section 8.4) for delivery to the source node, should be accompanied by some action which notifies the destination about a route back to the source node. The source node selects this mode of operation in the intermediate nodes by setting the 'G' flag. See section 8.5 for details about actions taken by the intermediate node in response to a RREQ with the 'G' flag set.

After broadcasting a RREQ, a node waits for a RREP. If the RREP is not received within NET_TRAVERSAL_TIME milliseconds, the node MAY rebroadcast the RREQ, up to a maximum of RREQ_RETRIES times. Each rebroadcast MUST increment the Broadcast ID field.

Data packets waiting for a route (i.e., waiting for a RREP after RREQ has been sent) SHOULD be buffered. The buffering SHOULD be FIFO. If

a RREQ has been rebroadcast RREQ_RETRIES times without receiving any RREP, all data packets destined for the corresponding destination SHOULD be dropped from the buffer and a Destination Unreachable message delivered to the application.

8.2.1. Controlling Route Request broadcasts

To prevent unnecessary network-wide broadcasts of RREQs, the source node SHOULD use an expanding ring search technique as an optimization. In an expanding ring search, the source node initially uses a TTL = TTL_START in the RREQ packet IP header and sets the timeout for receiving a RREP to 2 * TTL * NODE_TRAVERSAL_TIME milliseconds. Upon timeout, the source rebroadcasts the RREQ with the TTL incremented by TTL_INCREMENT. This continues until the TTL set in the RREQ reaches TTL_THRESHOLD, beyond which a TTL = NET_DIAMETER is used for each rebroadcast. Each time, the timeout for receiving a RREP is calculated as before. Each rebroadcast increments the Broadcast ID field in the RREQ packet. The RREQ can be rebroadcast with TTL = NET_DIAMETER up to a maximum of RREQ_RETRIES times.

When a RREP is received, the Hop Count used in the RREP packet is remembered as Last Hop Count in the routing table. When a new route to the same destination is required at a later time (e.g., upon route loss), the TTL in the RREQ IP header is initially set to this Last Hop Count plus TTL_INCREMENT. Thereafter, following each timeout the TTL is incremented by TTL_INCREMENT until TTL = TTL_THRESHOLD is reached. Beyond this TTL = NET_DIAMETER is used as before.

As a further optimization, timeouts MAY be determined dynamically via measurements, instead of using a statically configured value related to NODE_TRAVERSAL_TIME. To accomplish this, the RREQ may carry the timestamp via an extension field as defined in Section 11 to be carried back by the RREP packet (again via an extension field). The difference between the current time and this timestamp will determine the route discovery latency. The timeout may be set to be a small factor times the average of the last few route discovery latencies for the concerned destination. These latencies may be recorded as additional fields in the routing table.

If the optimizations described in this section are used, an expired routing table entry SHOULD NOT be expunged before DELETE_PERIOD. Otherwise, the soft state corresponding to the route (e.g., Last Hop Count) will be lost. In such cases, a longer routing table entry expunge time may be specified. Any routing table entry waiting for a RREP should not be expunged before RREP_WAIT_TIME.

8.3. Forwarding Route Requests

When a node receives a broadcast RREQ, it first checks to determine whether it has received a RREQ with the same Source IP Address and Broadcast ID within at least the last BROADCAST_RECORD_TIME milliseconds. If such a RREQ has been received, the node silently discards the newly received RREQ. The rest of this subsection describes actions taken for RREQs that are not discarded.

8.3.1. Processing Route Requests

When a node receives a RREQ, the node checks to determine whether it has an active route to the destination. If the node does not have an active route, it rebroadcasts the RREQ from its interface(s) but using its own IP address in the IP header of the outgoing RREQ. The Destination Sequence Number in the RREQ is updated to the maximum of the existing Destination Sequence Number in the RREQ and the destination sequence number in the routing table (if an entry exists) of the current node. The TTL or hop limit field in the outgoing IP header is decreased by one. The Hop Count field in the broadcast RREQ message is incremented by one, to account for the new hop through the intermediate node.

If the node, on the other hand, does has an active route for the destination, it compares the destination sequence number for that route with the Destination Sequence Number field of the incoming RREQ. If the existing destination sequence number is smaller than the Destination Sequence Number field of the RREQ, the node again rebroadcasts the RREQ just as if it did not have an active route to the destination.

The node generates a RREP (as discussed further in section 8.4) if either:

(i) it has an active route to the destination, and the node's existing destination sequence number is greater than or equal to the Destination Sequence Number of the RREQ, or

(ii) it is itself the destination.

The node always creates or updates a reverse route to the Source IP Address in its routing table. If a route to the Source IP Address already exists, it is updated only if either

(i) the Source Sequence Number in the RREQ is higher than the destination sequence number of the Source IP Address in the route table, or

(ii) the sequence numbers are equal, but the hop count as specified by the RREQ is now smaller than the existing hop count in the routing table.

When a reverse route is created or updated, the following actions are carried out:

1. the Source Sequence Number from the RREQ is copied to the corresponding destination sequence number;

2. the next hop in the routing table becomes the node broadcasting the RREQ (it is obtained from the source IP address in the IP header and is often not equal to the Source IP Address field in the RREQ message);

3. the hop count is copied from the Hop Count in the RREQ message;

4. the lifetime of the route is the higher of its current lifetime (for an active route) and current time plus REV_ROUTE_LIFE.

Even if the route is not updated because the existing route has a higher destination sequence number, but if it is scheduled to expire before REV_ROUTE_LIFE, its lifetime is still updated to be current time plus REV_ROUTE_LIFE.

This reverse route would be needed in case the node receives an eventual RREP back to the node which originated the RREQ (identified by the Source IP Address).

8.4. Generating Route Replies

If a node receives a route request for a destination, and either has a fresh enough route to satisfy the request or is itself the destination, the node generates a RREP message and unicasts it back to the node indicated by the Source IP Address field of the received RREQ. The node generating the RREP message copies the Source and Destination IP Addresses in RREQ message into the corresponding fields in the RREP message which is to be sent back toward the source of the RREQ. Additional operations are slightly different, depending on whether the node is itself the requested destination, or instead if it is an intermediate node with an admissible route to the destination.

As the RREP is forwarded to the source, the Hop Count field is incremented by one at each hop. Thus, when the RREP reaches the source, the Hop Count represents the distance, in hops, of the destination from the source.

8.4.1. Route Reply Generation by the Destination

If the generating node is the destination itself, it uses a destination sequence number at least equal to a sequence number generated after the last detected change in its neighbor set and at least equal to the destination sequence number in the RREQ. If the destination node has not detected any change in its set of neighbors since it last incremented its destination sequence number, it MAY use the same destination sequence number. The destination node places the value zero in the Hop Count field of the RREP.

The destination node copies the value MY_ROUTE_TIMEOUT into the Lifetime field of the RREP. Each node MAY make a separate determination about its value MY_ROUTE_TIMEOUT.

8.4.2. Route Reply Generation by an Intermediate Node

If node generating the RREP is not the destination node, but instead is an intermediate hop along the path from the source to the destination, it copies the last known destination sequence number in the Destination Sequence Number field in the RREP message.

The intermediate node places its distance in hops from the destination (indicated by the hop count in the routing table) in the Hop Count field in the RREP.

When the intermediate node updates its route table for the source of the RREQ, it puts the last hop node (from which it received the RREQ, as indicated by the source IP address field in the IP header) into the precursor list for the forward path route entry -- i.e., the entry for the Destination IP Address. Furthermore, the intermediate node puts the next hop towards the destination in the precursor list for the reverse route entry -- i.e., the entry for the Source IP Address field of the RREQ message data.

The intermediate node calculates the Lifetime field of the RREP by subtracting the current time from the expiration time in its route table entry.

8.5. Generating Gratuitous RREPs

When a node receives a RREQ and responds with a RREP, it does not forward the RREQ any further. If all incarnations of a single RREQ are replied to by intermediate nodes, the destination does not receive any copies of the RREQ. Hence, it does not learn of a route to the source node. This can be problematic if the source is attempting to establish a TCP session. In order that the destination learn of routes to the source node, the source node SHOULD set the gratuitous RREP ('G') flag in the RREQ if the session is going to be run over TCP, or if the destination should receive the gratuitous RREP for any other reason. Intermediate nodes receiving a RREQ with the 'G' flag set and responding with a RREP SHOULD unicast a gratuitous RREP to the destination node.

The RREP that is sent to the source of the RREQ is the same as before. The gratuitous RREP that is to be sent to the desired destination contains the following values in the RREP message fields:

Hop Count The Hop Count as received in the RREQ

Destination IP Address
The IP address of the node that generated the RREQ

Destination Sequence Number
The Source Sequence Number from the RREQ

Source IP Address
The IP address of the destination node

Lifetime The remaining lifetime of the route towards the destination node, as known by the intermediate node.

The gratuitous RREP is then sent to the next hop along the path to the destination node.

8.6. Forwarding Route Replies

When a node receives a RREP message, it first compares the Destination Sequence Number in the message with its own copy of destination sequence number for the Destination IP Address. The forward route for this destination is created or updated only if (i) the Destination Sequence Number in the RREP is greater than the node's copy of the destination sequence number, or (ii) the sequence numbers are the same, but the route is no longer active or the Hop Count in RREP is smaller than the hop count in route table entry. If a new route is created or the old route is updated, the next hop is the node from which the RREP is received, which is indicated by the source IP address field in the IP header; the hop count is the Hop Count in the RREP message plus one; the expiry time is the current time plus the Lifetime in the RREP message; the destination sequence number is the Destination Sequence Number in the RREP message.

The current node can now begin using this route to send data packets to the destination.

If the current node is not the source node as indicated by the Source IP Address in the RREP message AND a forward route has been created or updated as described before, the node consults its route table entry for the source node to determine the next hop for the RREP packet, and then forwards the RREP towards the source with its Hop Count incremented by one.

When any node generates or forwards a RREP, the precursor list for the corresponding destination node is updated by adding to it the next hop node to which the RREP is forwarded. Also, at each node the (reverse) route used to forward a RREP has its lifetime changed to current time plus ACTIVE_ROUTE_TIMEOUT.

If a node forwards a RREP over a link that is likely to have errors, the node MAY set the 'A' flag to require that the recipient of the RREP acknowledge receipt of the RREP by sending a RREP-ACK message back.

8.7. Hello Messages

A node MAY offer connectivity information by broadcasting local Hello messages as follows. Every HELLO_INTERVAL milliseconds, the node checks whether it has sent a broadcast (e.g., a RREQ or an appropriate layer 2 message) within the last HELLO_INTERVAL. If it has not, it MAY generate a broadcast RREP with TTL = 1, called a Hello message, with the message fields set as follows:

Destination IP Address
: The node's IP address.

Destination Sequence Number
: The node's latest sequence number.

Hop Count
: 0

Lifetime
: ALLOWED_HELLO_LOSS * HELLO_INTERVAL

A node MAY determine connectivity by listening for packets from its set of neighbors. If it receives no packets for more than ALLOWED_HELLO_LOSS * HELLO_INTERVAL milliseconds, the node SHOULD

assume that the link to this neighbor is currently broken. When this happens, the node SHOULD proceed as in Section 8.9.

8.8. Maintaining Local Connectivity

Each forwarding node SHOULD keep track of its active next hops (i.e., which next hops have been used to forward packets towards some destination within the last ACTIVE_ROUTE_TIMEOUT milliseconds). This is done by updating the Lifetime field of a routing table entry used to forward data packets to current time plus ACTIVE_ROUTE_TIMEOUT milliseconds. For purposes of efficiency, each node may try to learn which of these active next hops are really in the neighborhood at the current time using one or more of the available link or network layer mechanisms, as described below.

- Any suitable link layer notification, such as those provided by IEEE 802.11, can be used to determine connectivity, each time a packet is transmitted to an active next hop. For example, absence of a link layer ACK or failure to get a CTS after sending RTS, even after the maximum number of retransmission attempts, will indicate loss of the link to this active next hop.

- Passive acknowledgment can be used when the next hop is expected to forward the packet, by listening to the channel for a transmission attempt made by the next hop. If transmission is not detected within NEXT_HOP_WAIT milliseconds or the next hop is not a forwarding node (and thus is never supposed to transmit the packet) one of the following methods should be used to determine connectivity.

  * Receiving an ICMP ACK message from the next hop. The ICMP ACK message SHOULD be sent to a forwarding node by a next hop which is also the destination as in the in the IP header of the packet. This should be done only when this destination has not sent any packets to the concerned forwarding node within the last HELLO_INTERVAL milliseconds.

  * A RREQ unicast to the next hop, asking for a route to the next hop.

  * An ICMP Echo Request message unicast to the next hop.

If a link to the next hop cannot be detected by any of these methods, the forwarding node SHOULD assume that the link is broken, and take corrective action by following the methods specified in Section 8.9.

8.9. Route Error Messages

A node initiates a RERR message in three situations:

(i) if it detects a link break for the next hop of an active route in its routing table, or

(ii) if it gets a data packet destined to a node for which it does not have an active route, or

(iii) if it receives a RERR from a neighbor for one or more active routes.

For cases (i) and (ii), the destination sequence numbers in the routing table for the unreachable destination(s) are incremented by one. Then RERR is broadcast with the unreachable destination(s) and their incremented destination sequence number(s) included in the packet. For case (i), the unreachable destinations are the broken next hop, and any additional destinations which are now unreachable due to the loss of this next hop link. For case (ii), there is only one unreachable destination, which is the destination of the data packet that cannot be delivered. The DestCount field of the RERR packet indicates the number of unreachable destinations included in the packet.

For cases (i) and (ii), for each unreachable destination the node copies the value in the Hop Count route table field into the Last Hop Count field, and marks the Hop Count for this destination as infinity, and thus invalidates the route.

For case (iii) when a node receives a RERR message, for each unreachable destination included in the packet, the node determines whether the source node (as indicated by the source IP address in the IP header) forwarding the RERR packet is its own next hop used to reach this destination. If so, the node takes the following actions:

(a) updates the corresponding destination sequence number with the Destination Sequence Number in the packet, and

(b) marks the Hop Count for this destination as infinity, and thus invalidates the route.

(c) checks the precursor list for this destination. If one or more of these precursor lists are non-empty, the node creates a RERR message, including as unreachable each destination with a non-empty precursor list. It also includes their destination sequence numbers, and then broadcasts this RERR message.

When a node receives a RERR message, it always updates its destination sequence number(s) for the unreachable destination(s) included in the packet using the corresponding sequence numbers included in the message. When a node broadcasts a RERR message, it always deletes the precursor list of each unreachable destination included in the message.

When a node invalidates a route to a neighboring node, it must also delete that neighbor from any precursor lists for routes to other nodes. This prevents precursor lists from containing stale entries of neighbors with which the node is no longer able to communicate. The node should inspect the precursor list of each destination entry in its routing table, and delete the lost neighbor from any list in which it appears.

8.9.1. Local Repair

When a link break in an active route occurs, the node upstream of that break MAY choose to repair the link locally if the destination is no farther than MAX_REPAIR_TTL hops away. To repair the link break itself, it increments the sequence number for the destination and then broadcasts a RREQ for that destination. The TTL of the RREQ should initially be set to the following value:

max(MIN_REPAIR_TTL, 0.5 TTL to source) + LOCAL_ADD_TTL .

Thus, local repair attempts should never be visible to the source node, and will always have minimum TTL equal to MIN_REPAIR_TTL + LOCAL_ADD_TTL. The node initiating the repair then waits the discovery period to receive RREPs in response to the RREQ. If, at

the end of the discovery period, it has not received a RREP for that destination, it proceeds as described in Section 8.9 by creating a RERR message for that destination.

On the other hand, if the nodes does receive one or more RREPs during the discovery period, the node proceeds as described in Section 8.6, creating a route table entry for that destination. It then compares the hop count of the new route with the value in the last hop count route table entry for that destination. If the hop count of the newly determined route to the destination is greater than the hop count of the previously known route, as recorded in the last hop count field, the node MAY create a RERR message for the destination and send this message to the source node. The node sets the 'N' flag of the RERR, and then broadcasts this message if it has one or more precursor nodes for this route table entry.

A node which receives a RERR message with the 'N' flag set MUST NOT delete the route to that destination. The only action taken should be the retransmission of the message, if the RERR arrived from the next hop along that route, and if there are one or more precursor nodes for that route to the destination. When the source node receives a RERR message with the 'N' flag set, if this message came from its next hop along its route to the destination then the source node MAY choose to reinitiate route discovery, as described in Section 8.2.

Local repair of link breaks in active routes sometimes results in increased path lengths to those destinations. Repairing the link locally is likely to increase the number of data packets which are able to be delivered to the destinations, since data packets will not be dropped as the RERR travels to the source node. Sending a RERR to the source node after locally repairing the link break allows the source to find a fresh route to the destination which is more optimal based on current node positions. However, it does not require the source node to rebuild the route, as the source may be done, or nearly done, with the data session.

When a link breaks along an active route, there are often multiple destinations which become unreachable. The node which is upstream of the broken link tries an immediate local repair for only the one destination towards which the packet was traveling. Other routes using the same link MUST be marked as broken, but the node handling

the local repair MAY flag each such newly broken route as locally repairable; this local repair flag in the route table MUST be reset when the route times out (i.e., after the route has been not been active for ACTIVE_ROUTE_TIMEOUT). Before the timeout occurs, these other routes will be repaired as needed when packets arrive for the other destinations. Alternatively, depending upon local congestion, the node MAY begin the process of establishing local repairs for the other routes, without waiting for new packets to arrive.

8.10. Route Expiry and Deletion

If the Lifetime of an active routing entry expires, the following actions are taken.

1. The entry is invalidated by copying the Hop Count to the Last Hop Count field and then making the Hop Count infinity.

2. The destination sequence number of this routing entry is incremented by one.

3. The Lifetime field is updated to current time plus DELETE_PERIOD. Before this time, the entry MUST NOT be deleted.

Note that the Lifetime field plays dual role -- for an active route it is the expiry time, and for an invalid route it is the deletion time.

These actions are also taken whenever a route entry is invalidated for any reason, for example, for link breakage or receiving a RERR.

If a data packet is received for an invalid route, the Lifetime field is always updated to current time plus DELETE_PERIOD. The determination of DELETE_PERIOD is discussed in Section 12

8.11. Actions After Reboot

A node participating in the ad hoc network must take certain actions after reboot as it will have lost its prior sequence number and as well as its last known sequence numbers for various other destinations. However, there may be neighboring nodes which

are using this node as an active next hop. This can potentially create routing loops. To prevent this possibility, each node on reboot waits for DELETE_PERIOD. In this time, it does not respond to any routing packets. However, if it receives a data packet, it broadcasts a RERR as described in subsection 8.9 and resets the waiting timer (Lifetime) to expire after current time plus DELETE_PERIOD.

It can be shown that by the time the rebooted node comes out of the waiting phase and becomes an active router again, none of its neighbors will be using it as an active next hop any more. Its own sequence number gets updated once it receives a RREQ from any other node, as the RREQ always carries the maximum destination sequence number seen en route.

8.12. Interfaces

Because AODV should operate smoothly over wired, as well as wireless, networks, and because it is likely that AODV will also be used with multi-homed radios, the interface over which packets arrive must be known to AODV whenever a packet is received. This includes the reception of RREQ, RREP, and RERR messages. Whenever a packet is received from a new neighbor, the interface on which that packet was received is recorded into the route table entry for that neighbor, along with all the other appropriate routing information. Similarly, whenever a route to a new destination is learned, the interface through which the destination can be reached is also recorded into the destination's route table entry.

When multiple interfaces are available, a node receiving and rebroadcasting a RREQ message rebroadcasts that message on all interfaces. Similarly, when a node needs to transmit a RERR, it should only broadcast it on those interfaces which have precursor nodes for that route.

9. AODV and Aggregated Networks

AODV has been designed for use by mobile nodes with IP addresses that are not necessarily related to each other, to create an ad hoc network. However, in some cases a collection of mobile nodes MAY

operate in a fixed relationship to each other and share a common subnet prefix, moving together within an area where an ad hoc network has formed. Call such a collection of nodes a ‘‘subnet’’. In this case, it is possible for a single node within the subnet to advertise reachability for all other nodes on the subnet, by responding with a RREP message to any RREQ message requesting a route to any node with the subnet routing prefix. Call the single node the ‘‘subnet router’’. In order for a subnet router to operate the AODV protocol for the whole subnet, it has to maintain a destination sequence number for the entire subnet. In any such RREP message sent by the subnet router, the Prefix Size field of the RREP message MUST be set to the length of the subnet prefix. Other nodes sharing the subnet prefix SHOULD NOT issue RREP messages, and SHOULD forward RREQ messages to the subnet leader.

10. Using AODV with Other Networks

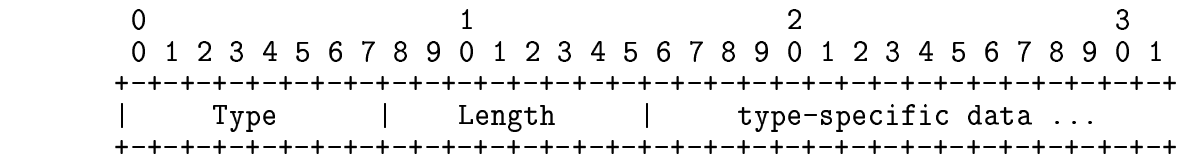
In some configurations, an ad hoc network may be able to provide connectivity between external routing domains that do not use AODV. If the points of contact to the other networks can act as subnet routers (see Section 9) for any relevant networks within the external routing domains, then the ad hoc network can maintain connectivity to the external routing domains. Indeed, the external routing networks can use the ad hoc network defined by AODV as a transit network.

In order to provide this feature, a point of contact to an external network (call it an Infrastructure Router) has to act as the subnet router for every subnet of interest within the external network for which the Infrastructure Router can provide reachability. This includes the need for maintaining a destination sequence number for that external subnet.

If multiple Infrastructure Routers offer reachability to the same external subnet, those Infrastructure Routers have to cooperate (by means outside the scope of this specification) to provide consistent AODV semantics for ad hoc access to those subnets.

11. Extensions

RREQ and RREP messages have extensions defined in the following format:



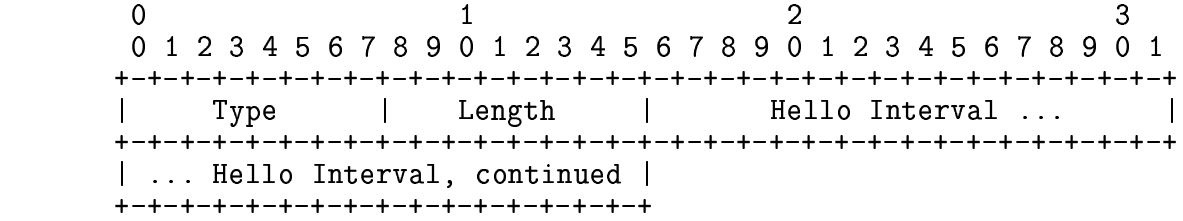
where:

Type 1

Length The length of the type-specific data, not including the Type and Length fields of the extension.

Extensions with types between 128 and 255 may NOT be skipped. The rules for extensions will be spelled out more fully, and conform with the rules for handling IPv6 options.

11.1. Hello Interval Extension Format



Type 2

Length 4

Hello Interval
The number of milliseconds between successive transmissions of a Hello message.

The Hello Interval extension MAY be appended to a RREP message with TTL == 1, to be used by a neighboring receiver in determine how long to wait for subsequent such RREP messages (i.e., Hello messages; see section 8.7).

12. Configuration Parameters

This section gives default values for some important values associated with AODV protocol operations. A particular mobile node may wish to change certain of the parameters, in particular the NET_DIAMETER, NODE_TRAVERSAL_TIME, MY_ROUTE_TIMEOUT, ALLOWED_HELLO_LOSS, RREQ_RETRIES, and possibly the HELLO_INTERVAL. In the latter case, the node should advertise the HELLO_INTERVAL in its Hello messages, by appending a Hello Interval Extension to the RREP message. Choice of these parameters may affect the performance of the protocol.

Parameter Name	Value
ACTIVE_ROUTE_TIMEOUT	3,000 Milliseconds
ALLOWED_HELLO_LOSS	2
BROADCAST_RECORD_TIME	2 * NET_TRAVERSAL_TIME
DELETE_PERIOD	see note below
HELLO_INTERVAL	1,000 Milliseconds
LOCAL_ADD_TTL	2
MAX_REPAIR_TTL	0.3 * NET_DIAMETER
MY_ROUTE_TIMEOUT	2 * ACTIVE_ROUTE_TIMEOUT
NET_DIAMETER	35
NEXT_HOP_WAIT	NODE_TRAVERSAL_TIME + 10
NODE_TRAVERSAL_TIME	40
REV_ROUTE_LIFE	NET_TRAVERSAL_TIME
NET_TRAVERSAL_TIME	3 * NODE_TRAVERSAL_TIME * NET_DIAMETER / 2
RREQ_RETRIES	2
TTL_START	1
TTL_INCREMENT	2
TTL_THRESHOLD	7

DELETE_PERIOD should be an upper bound on the time for which an upstream node A can have a neighbor B to be an active next

hop for destination D, while B has invalidated the route to D. Beyond this time B can delete the route to D. The determination of the upper bound somewhat depends on the characteristics of the underlying link layer. For example, if the link layer feedback is used to detect loss of link DELETE_PERIOD must be at least ACTIVE_ROUTE_TIMEOUT. If there is no feedback and hello messages must be used, DELETE_PERIOD must be at least maximum of ACTIVE_ROUTE_TIMEOUT and ALLOWED_HELLO_LOSS * HELLO_INTERVAL. If hello messages are received from a neighbor but data packets to that neighbor are lost, (due to temporary link asymmetry, e.g.) we have to make more concrete assumptions about the underlying link layer. We assume that such asymmetry cannot persist beyond a certain certain time, say, a multiple K of ALLOWED_HELLO_LOSS * HELLO_INTERVAL. In other words, it cannot not be the case that a node receives K subsequent hello messages from a neighbor, while that same neighbor fails to receive any data packet from the node in this period. This is a reasonable assumption as this AODV specification works only with symmetric links. Covering all possibilities,

DELETE_PERIOD = K * max (ACTIVE_ROUTE_TIMEOUT, ALLOWED_HELLO_LOSS * HELLO_INTERVAL) (K = 5 is recommended).

NET_DIAMETER measures the maximum possible number of hops between two nodes in the network. NODE_TRAVERSAL_TIME is a conservative estimate of the average one hop traversal time for packets and should include queueing delays, interrupt processing times and transfer times. ACTIVE_ROUTE_TIMEOUT SHOULD be set to a longer value (at least 10,000 milliseconds) if link-layer indications are used to detect link breakages such as in IEEE 802.11 [2] standard. TTL_START should be set to at least 2 if Hello messages are used for local connectivity information. Performance of the AODV protocol is sensitive to the chosen values of these constants, which often depend on the characteristics of the underlying link layer protocol, radio technologies etc.

13. Security Considerations

Currently, AODV does not specify any special security measures. Route protocols, however, are prime targets for impersonation attacks, and must be protected by use of authentication techniques involving generation of unforgeable and cryptographically strong

message digests or digital signatures. It is expected that, in environments where security is an issue, that IPSec authentication headers will be deployed along with the necessary key management to distribute keys to the members of the ad hoc network using AODV.

14. Acknowledgments

We acknowledge with gratitude the work done at University of Pennsylvania within Carl Gunter's group, as well as at Stanford and CMU, to determine some conditions (especially involving reboots and lost RERRs) under which previous versions of AODV could suffer from routing loops. Contributors to those efforts include Karthikeyan Bhargavan, Joshua Broch, Dave Maltz, Madanlal Musuvathi, and Davor Obradovic. The idea of a DELETE_PERIOD, for which expired routes (and, in particular, the sequence numbers) to a particular destination must be maintained, was also suggested by them.

We also acknowledge the comments and improvements suggested by SJ Lee (especially regarding local repair) and Mahesh Marina.
